Abstract - Artificial neural networks (ANNs) are used for content based image retrieval (CBIR). Training of a neural network requires that the user specifies the network structure and sets the learning parameters. In this study, the optimum design of ANN’s for retrieval of images is investigated. We use test image datasets in a series of experiments that evaluate the effects on network performance (measured in terms of the Mean Square Error and number of iteration (time required for training)) of different choices of network size and structure, network parameters, training samples size. We use a test image database of 1000 images including 10 classes. Each class has 100 images. The backpropagation algorithm, also called the generalized delta rule, was used for neural network training. An activation function was hyperbolic tangent. Experiments show that with used category of images optimal number of neurons in hidden layer is half of number of images in used training set. We intend to design small CBIR system for educational purposes and potentially for mobility environment.

Keywords - Artificial neural networks, backpropagation algorithm, color histogram, content-based image retrieval.

I. DATA USED AND METHODOLOGY

Content-based image retrieval, uses the visual contents of an image such as color, shape, texture, and spatial layout to represent and index the image [1]. A visual content descriptor can be either global or local. A global descriptor uses the visual features of the whole image, whereas a local descriptor uses the visual features of regions or objects to describe the image content. To obtain the local visual descriptors, an image is often divided into parts first. The simplest way of dividing an image is to use a partition, which cuts the image into tiles of equal size and shape. A simple partition does not generate perceptually meaningful regions but is a way of representing the global features of the image at a finer resolution. Color is the most extensively used visual content for image retrieval [2], [3], [4], [6], [8], [9]. Its three-dimensional values make its discrimination potentiality superior to the single dimensional gray values. Each pixel of the image can be represented as a point in a 3D color space. Commonly used color space for image retrieval include RGB, Munsell, CIE L*a*b*, CIE L*u*v*, HSV (or HSL, HSB), and opponent color space.

There is no agreement on which is the best. RGB space is a widely used color space for image display. It is composed of three color components red, green, and blue. These components are called "additive primaries" since a color in RGB space is produced by adding them together. The color histogram serves as an effective representation of the color content of an image if the color pattern is unique compared with the rest of the data set. The color histogram is easy to compute and effective in characterizing both the global and local distribution of colors in an image. In addition, it is robust to translation and rotation about the view axis and changes only slowly with the scale, occlusion and viewing angle. Since any pixel in the image can be described by three components in a certain color space (for instance, red, green, and blue components in RGB space, or hue, saturation, and value in HSV space), a histogram, i.e., the distribution of the number of pixels for each quantized bin, can be defined for each component. Clearly, the more bins a color histogram contains, the more discrimination power it has. However, a histogram with a large number of bins will not only increase the computational cost, but will also be inappropriate for building efficient indexes for image databases.

The human visual system can perceive thousands of colors and about 50 gray levels (luminance levels) [13]. Existing retrieval systems use about 200 colors, which allow the use of four to seven luminance levels. However this is not enough, because a "color group" contains too large a luminance variation. Luminance is one component in some color spaces, for example Lab and Luv. Some systems [10], [11, [14] use a luminance histogram as one of the features.

The color RGB image will be converted to the YUV (Y – luminence; U, V – hrominance) color space with some equations. These equations assume that the red, green, and blue components have values between 0.0 and 1.0. Since this range is typical represented using 8-bit values between 0 and 255, they need to be scaled and processed as floating-point numbers:

\[
Y = .299R + .587G + .114B \\
U = -.147R - .289G + .437B \\
V = .615R + .515G - .100B
\]

The Y component will be quantized with a uniform quantizer to N different values. A normalized luminance histogram will be built from the quantized Y values of each pixel. In this histogram every index corresponds to one of these luminance values.
We are using a test image database of 1000 images including 10 classes, which can be downloaded from the website: http://wang.ist.psu.edu/ jwang/test1.tar. Each class has 100 images.

Artificial neural networks (ANNs) are used in the image retrieval[12]. Backpropagation learning algorithm, also called the generalized delta rule, was an iterative gradient descent training procedure[13].

A specialized application developed in C# was used as software environment for performing of workflow.

II. TRAINING OF MULTILAYER PERCEPTRON (MLP)

An artificial neural network (ANN) or commonly just neural network (NN) is an interconnected group of artificial neurons that uses a mathematical model or computational model for information processing based on a connectionist approach to computation. In most cases an ANN is an adaptive system that changes its structure based on external or internal information that flows through the network.

An artificial neuron is a device with many inputs and one output. The neuron has two modes of operation; the training mode and the using mode. In the training mode, the neuron can be trained to fire (or not), for particular input patterns. In the using mode, when a taught input pattern is detected at the input, its associated output becomes the current output. If the input pattern does not belong in the taught list of input patterns, the firing rule is used to determine whether to fire or not.

An important application of neural networks is pattern recognition. Pattern recognition can be implemented by using a feed-forward neural network that has been trained accordingly. During training, the network is trained to associate outputs with input patterns. When the network is used, it identifies the input pattern and tries to output the associated output pattern.

The commonest type of artificial neural network consists of three groups, or layers, of units: a layer of "input" units is connected to a layer of "hidden" units, which is connected to a layer of "output" units.

- The activity of the input units represents the raw information that is fed into the network.
- The activity of each hidden unit is determined by the activities of the input units and the weights on the connections between the input and the hidden units.
- The behavior of the output units depends on the activity of the hidden units and the weights between the hidden and output units.

This simple type of network is interesting because the hidden units are free to construct their own representations of the input. The weights between the input and hidden units determine when each hidden unit is active, and so by modifying these weights, a hidden unit can choose what it represents.

The MLP classifiers training process depends on a set of parameters. The value of these parameters can be varied to different extent (degree) depending on different conditions of experiment. There are the following parameters which were varied during the experiment:

- Number of training samples;
- Stopping criterion for the training process (error or number of iterations);
- Number of input nodes;
- Learning rate;
- Number of hidden layers;
- Number of hidden nodes;
- Type of an activation function

Training the network can be summarized as follows:

- Apply input to the network.
- Calculate the output.
- Compare the resulting output with the desired output for the given input. This is called the error.
- Modify the weights for all neurons using the error.
- Repeat the process until the error reaches an acceptable value (e.g. error < 1%), which means that the NN was trained successfully, or if we reach a maximum count of iterations, which means that the NN training was not successful.

III. PRACTICAL ASPECTS OF NEURAL NETWORK IMPLEMENTATION

We will present in this subsection some of the practical aspects related to the real implementation of neural networks. We will discuss the normalization of the data set, the splitting of the data set in training and test sets, the architecture of the neural network, the stopping criteria and several other practical conditions.

Let us assume that the original data set was already pre-processed and that problems with missing values and noise or outliers were already treated. In other words, we assume that our data set is a "clean" data set. The work on data preparation for neural network data analysis in [14] presents a study on several aspects regarding data pre-processing.

The first thing that usually one must do to this clean data set is to perform a data normalization, or standardization, to avoid that higher inputs assume a more important role in the learning process than small inputs. The usual normalization processes transform the data so that:

- every feature of the data is scaled in the interval [0; 1] or [-1; 1], or
- every feature is standardized to have zero mean and unitary standard deviation.

The next step is to choose the architecture of the neural network. There is no rule specifying the number of hidden layers and the number of neurons in each hidden layer. We mentioned earlier that a neural network with one hidden layer can approximate arbitrarily close any decision boundary, so, for most problems, a two-layer neural network will be sufficient. A three-layer network can be considered if a data set is particularly hard to train.
Although there are some works suggesting formulas for determining the number of neurons in the hidden layer (examples are [15], [16], [18]), we still think that there is nothing like experimentation. Experiments should be performed with a range of values for the number of hidden neurons that must be chosen taking into account the complexity of the problem. There are also some techniques consisting on starting with a high complex neural network and then, during training, performing a pruning by eliminating those weights with small influence (very low value) [20] – [22].

As for the initial values for the weights and bias, we should use random small values. This is done to prevent the possibility that some of the initial output values could be in the saturation region of the activation function. As activation functions we use, in our experiments, the hyperbolic tangent in all neurons.

The program trains the network using bitmap images that are located in a folder. This folder must be in the following format:

- There must be one (input) folder that contains input images ['*.jpg'].
- Each image's name is the target (or output) value for the network (the bins of gray histogram of the image are the inputs).

The input layer consisted of number of neurons, corresponding to bins of used type of histogram for image from training set. The hidden layer had varying number of neurons in our experiment and the output layer had number of neurons equal to number of images in particular training set.

The backpropagation algorithm was used for neural network training. An activation function was hyperbolic tangent. A network structure was trained with the parameters listed in Table 1.

IV. IMPLEMENTATION

We implemented our CBIR system in C# using Windows-Forms. The database are images stored under folder and the trained network is stored as a binary serialization into a file. The network file is called *.net. Each time the system is loaded, the network is loaded and de-serialized into the main memory, and whenever the search takes place it is ready for comparisons.

Query formation by the user is done using the method of example query. Wherever the user wants to find the image he supplies the image, and the system should return similar pictures.

The system presents the top 2 results for the image query. Thus allowing the user to see some possible suggestions with appropriate confidence.

V. EXPERIMENTS AND RESULTS:

We experimented with our system using the following techniques:

- Simple (Global) Histogram.
- Local (Areas based) Histogram.

Experimental platform is PC AMD Sempron 1.6 GHz with Windows XP.

The normalized grayscale histogram extracted from an image is a 256 dimensional vector that is contained in the histogram space $S_H$ (represented by a unit hypercube), and used H as input vector X.

VI. CONCLUSIONS:

It is known that histogram is quite primitive and mainly insufficient way for CBIR purposes. However, with certain image characteristics it may be useful, and works well.

Experiments show that with used category of images optimal number of neurons in hidden layer is half of number of images in used training set.

Despite used low level feature (gray-level histogram) as input vector trained artificial neural networks works perfectly on training set of images, but with growth of training set rapidly is increasing training time which is inappropriate for practical solutions.

Generic CBIR will have to wait both for algorithmic advances in image understanding and advances in computer hardware, especially when constraints on real time performance are added.
